Abstract – The quality concept involves all activities ensuring that a product meets all fabrication requirements. The quality tests validate the performance of a product to perform reliably its tasks. In this paper, we present the implementation of a software solution for tests used in statistical control. We designed an application for either personal computer or mobile phone that will improve procedures for quality engineering.

Keywords - statistical control, quality engineering, software application

I. INTRODUCTION

The statistical control is based on a mathematical report carried out in a previous step. This method uses the information provided by a sample, which is subsequently generalized to the entire lot. As a prerequisite condition, the sample has to be representative for the entire lot studied. [1]

The STAS 6085/72 standard recommends three methods for sample selection, based on:
- random numbers list;
- blind extraction;
- multi-step procedure.

The control based on the products attributes is used when the features to be checked are measurable or not, but the value of these features must meet an imposed tolerance range.

To make a decision on the quality of a controlled lot (accepting or rejecting decision), it is essential to calculate the following specific parameters:
- the size of the sample to be checked – n;
- the maximum number of faults admitted in the sample to accept the lot – A;
- the minimum number of faults in the sample above which the lot is rejected – R.

In order to calculate these three parameters, we created specific software, especially designed for this purpose. This software will use the following input data:
- N = the lot size; the lot components need to be as homogenous as possible;
- NC = the control level; there are seven standardized levels. The first control levels (S1-S4) are specific levels and the next three (I-III) is control levels of general character.

When the control level is moving from level S1 to III, the sample size is increase. Therefore, when the control level is increase, the quality also is increase.
- AQL - the accepted quality level. The statistical control involves two risks:
  - α - The provider risk: to reject a product lot actually good;
  - β - The beneficiary risk: to accept the lot that would have been rejecting by checking the entire lot.

Figure 1. The operative feature

Operative Feature

Legend:
- α - the lot of the manufacturer to have it’s lot rejected after the products are verified, but the lot would be accepted if different parts would be made piece by piece;
- β - the lot of the beneficiary which accepts the lot, even though an 100% control would indicate that the lot satisfies the contractual demands;
- p1 - the percentage of defects from which the manufacturer can have it’s lot rejected;
- p2 - the percentage of defects from which the beneficiary doesn’t accept the lot.

- Rigorousness level of the control – is relating to the sample size and the number of faults needed in order to reject the lot. The following levels of rigorousness apply normal, severe or low. In the usual practice, the “normal” level is applied. However, if five successive lots are rejected under this level, it is necessary to shift the rigorousness level to the “severe” control. In this situation, we use smaller values for accepted (A) and rejected (R) parameters. If there is previous information on products’ quality, the rigorousness level can be shift to “low” control.

- The type of test- can be:
  - single: the decision to accept or reject the lot is made taking into account the results of a single extraction;
- **double**: one or two samples are extracted, after which a decision is made on accepting or rejecting the lot or on the need of another extraction;
- **multiple**: one, two or more samples are extracted; based on the quality of each sample, we decide to accept or reject the lot or to make another extraction; the maximum number of extractions is set to seven.

Here we present this software application specially designed to help the statistical control during lots’ testing.

## II. THE SOFTWARE APPLICATION

We designed a software application accessed through a web portal able to calculate the specific parameters used in the quality control: n, A, and R, based on input data decided beforehand. This application implemented in HTML/CSS with JQuery, is base on Bootstrap 3, which makes it “responsive” (the application can be also use on mobile phones with “Android” operating system).

This application can be open in any browser (Google Chrome, Mozilla Firefox, and Internet Explorer) available for personal computers (PC). To open the application on a PC, one must access the folder where the executable file “index.html” is situated and double click on the icon. This makes launching the application in the browser installed on that PC. [2]

![Figure 2. The installing of the application for PC](image)

On the mobile phone, we need first to install the application “Open in Browser”; then, this application can be open using any browser on the device.

![Figure 3. The installing of the application for mobile phone](image)

This application has five input data (N, Nc, AQL, Rigoroussness level of the control and The type of test). The application for PC has a graphical interface like in Fig. 4. Here, the user will specified the values for those five input parameters for this test.

In next step, are determinate those three values for output parameters from specifically correlation between elements from database.

The most important element for a statistical control is the value for AQL.

Two of output data are the maximum number of faults admitted in the sample to accept the lot – A and the minimum number of faults in the sample above which the lot is rejected – R.

There is a math addiction between those parameters.

For the single test: \( R = A + 1 \), and for double test or multiplying test, this addiction is applied only for the last pair of values.

Only for reduced test this relation is not exist, because this test is make in specific conditions.

III. CALCULATING THE SPECIFIC PARAMETERS FOR STATISTICAL CONTROL

We present below the use of the application to calculate the parameters for different types of tests.

Single test

Consider a lot of a size of $N = 5000$. Starting from the premise that secondary faults exist in the lot, we set a value of $AQL = 1.5$ and a control level of $N_C = II$, and we want to calculate the sample size ($n$) and the level for accepting (A) or rejecting (B) the lot.

First, we specify the input parameters, as in Fig. 6: $N$ - the lot size, $AQL$ - the acceptable quality level, $N_C$ - the control level.

After we specified the input parameters, the operator can click on the button “Calculate”. This will trigger the pop-up of the output data (Fig. 7.).

$n$ - the sample volume
$A$ - the number of acceptance
$R$ - the number of rejection

Figure 6. The input data for the single test

Figure 7. The experimental results
Double test

Consider a lot of a size of $N = 70,000$. Starting from the premise that secondary faults exist in the lot, we set a value of $AQL=10$ and a control level of $N_{C} = I$, and we want to calculate the sample size ($n$) and the level for accepting ($A$) or rejecting ($B$) the lot. First, we specify the input parameters, as in Fig.8: $N$ - the lot size, $AQL$ - the acceptable quality level, $N_{C}$ - the control level.

After we specified the input parameters, the operator can click on the button “Calculate”. This will trigger the pop-up of the output data (Fig.9).

$n$ - the sample volume
$A$ - the number of acceptance
$R$ - the number of rejection

The multiple tests

In this example, the lot size is $N = 100,000$. Starting from the premise that secondary faults exist, we set the value for $AQL=0.15$ and the control level $N_{C} = II$ as in Fig.5. We calculate the sample size ($n$) and the level for accepting ($A$) or rejecting ($R$) the lot as in Fig. 10.

Figure 8. The input data for double test

![Figure 8](image)

Figure 9. The output data for double test

![Figure 9](image)

Figure 10. The input data for multiple test

![Figure 10](image)

Figure 11. The experimental results for multiple test

![Figure 11](image)
The normal severe test

In this example, the lot size is \( N = 5000 \). Starting from the premise that that secondary faults exist, we set the value for AQL=1.5 and the control level \( N_c = II \) (Fig. 10.). We calculate the sample size (n) and the level for accepting (A) or rejecting (R) the lot. [4]

In next picture, we can see a math addiction between A and R.
This test can be use when five consecutive tests for the same producer indicated a fault result.

The normal reduced test

In this example, the lot size is \( N = 5000 \). Starting from the premise that that secondary faults exist, we set the value for AQL=1.5 and the control level \( N_c = II \) (Fig. 12.). We calculate the sample size (n) and the level for accepting (A) or rejecting (R) the lot.

In next picture, we can see that between A and R does not any mathematical relation, because this is a special test. This is use when we know more information about the producer and we are according a credit for this producer.
CONCLUSION

The quality assurance has a special importance in all aspects of life. If a single element involved in such a complex system does not meet the required quality standards, it can result in a malfunction of the system.

The statistical control at reception is one of the very important steps in determining the products’ quality. There are many methods for meeting this goal, but we proposed and designed an online software application to resolve this issue. Among the important advantages of our application, we can enumerate the use on either personal computer or mobile phone, easiness to use, and the need of minimal hardware and software resources.

This application will be used to quality engineering laboratories and it is develop in collaboration with the students from Electronics profile from the University of Pitesti.
